

QCD at Finite Baryon Density: Chiral Symmetry Restoration and Color Superconductivity

We use a variational procedure to study finite density QCD in an approximation in which the interaction between quarks is modelled by that induced by instantons. We find that uniform states with conventional chiral symmetry breaking have negative pressure with respect to empty space at all but the lowest densities, and are therefore unstable. This is a precisely defined phenomenon which motivates the basic picture of hadrons assumed in the MIT bag model, with nucleons as droplets of chiral symmetry restored phase. This suggests that the phase transition to a chirally symmetric phase occurs by percolation of preexisting droplets of the symmetric phase, and in these proceedings we expand upon our previous presentation of this observation. At all densities high enough that the chirally symmetric phase fills space, color symmetry is broken by the formation of a $\langle qq \rangle$ condensate of quark Cooper pairs. A plausible ordering scheme leads to a substantial gap in a Lorentz scalar channel involving quarks of two colors.

§1. Introduction

In my lecture at YKIS97, I presented recent work done with Mark Alford and Frank Wilczek¹⁾ on QCD at finite baryon density. This contribution to a large extent follows that paper, although in Section 3 I have given a significantly expanded treatment of chiral symmetry restoration.

Asymptotic freedom leads us to expect that at high baryon density quarks behave nearly freely and form large Fermi surfaces, with interactions between the quasiparticles at the Fermi surfaces which become weak at asymptotically high density. Since the quark-quark interaction is attractive in the color $\mathbf{\bar{3}}$ channel, BCS pairing of quarks will occur no matter how weak the interaction. Cooper pairs of quarks cannot be color singlets, and so a $\langle qq \rangle$ condensate inevitably breaks color symmetry. This breaking is analogous to the breaking of electromagnetic gauge invariance in superconductivity. In this color superconducting phase, the Higgs mechanism operates and five of the eight gluons become massive, and the $U(1)$ gauge boson which remains massless is a linear combination of the photon and a gluon. The proposed symmetry breaking in diquark channels is of course quite different from chiral symmetry breaking in QCD at zero density, which occurs in color singlet quark-antiquark channels.

Our goal is to explore such new forms of ordering in the context of a model which is definite, qualitatively reasonable, and yet sufficiently tractable that likely patterns of symmetry breaking and rough magnitudes of their effects can be identified concretely. In the course of looking for new patterns we will need to discuss the fate

^{*)} Email address: krishna@ctp.mit.edu.

of the old one, and here a surprise emerges: we find that a uniform phase with broken chiral symmetry is unstable at any nonzero density, and therefore unphysical. At all but the lowest densities, this instability is signalled by negative pressure, which presumably triggers the break-up of the uniform state into regions of high density separated by empty space. This suggests that in this model, baryons can be identified with high baryon density droplets containing massless quarks, and suggests that chiral symmetry restoration at high density and zero temperature can be treated as a percolation (or better, as we shall see, “unpercolation”) process. In these proceedings, I give an alternate description of these phenomena, which has virtues both as a way to better understand the zero temperature physics of concern to us here and because it can be extended to nonzero temperatures.²⁾ We construct the thermodynamic potential for the model at hand, and discover that it has a first order transition between a state with zero baryon density and broken chiral symmetry (namely the vacuum) and a state with chiral symmetry restored and with a baryon density n_0 greater than that of nuclear matter. Ordinary nuclear matter can then be identified within the model as being in the mixed phase of this first order transition: it consists of droplets of the high density phase separated by regions of vacuum. Chiral symmetry restoration occurs as the first order transition to the high density phase is completed as the density is increased and the droplets merge. The high density phase is a color superconductor, as we discuss in Section 4.³⁾

§2. Model

We already alluded to the fact that asymptotic freedom suggests qualitatively new types of order at very high density. This regime has been studied⁴⁾ by approximating the interquark interactions by one gluon exchange, which is in fact attractive in the color antitriplet channel. Perturbative treatments cannot, by their nature, do full justice to a problem whose main physical interest arises at moderate densities. To get more insight into the phenomena, and in particular to make quantitative estimates, it seems appropriate to analyze a tractable, physically motivated model.

We have done a variational treatment of a two-parameter class of models having two flavors and three colors of massless quarks. The kinetic part of the Hamiltonian is that for free quarks, while the interaction Hamiltonian is a slight idealization of the instanton vertex⁵⁾ from QCD, explicitly:

$$H_I = -K \int d^3x \bar{\psi}_{R1\alpha} \psi_{Lk}^\gamma \bar{\psi}_{R2\beta} \psi_{Ll}^\delta \varepsilon^{kl} (3\delta^\alpha_\gamma \delta^\beta_\delta - \delta^\alpha_\delta \delta^\beta_\gamma) + \text{h.c.} , \quad (2.1)$$

where $1, 2, k, l$ are flavor indices, $\alpha, \beta, \gamma, \delta$ are color indices, repeated indices are summed, and the spinor indices are not shown. The overall sign is chosen negative for later convenience, so that $K > 0$ results in chiral symmetry breaking. H_I is not yet a good representation of the instanton interaction in QCD: in order to mimic the effects of asymptotic freedom, we must modify it in such a way that the interaction decreases with increasing momentum. We write H_I as a mode expansion in momentum space involving creation and annihilation operators and spinors, and multiply the result by

a product of form factors each of the form $F(p) = [\Lambda^2/(p^2 + \Lambda^2)]^\nu$, one for each of the momenta of the four fermions. This factorized form is taken for later convenience, and is an idealization. Λ , of course, is some effective QCD cutoff scale, which one might anticipate should be in the range 300 – 1000 MeV. ν parametrizes the shape of the form factor; we consider $\nu = 1/2$ and $\nu = 1$. Since the interaction we have chosen is not necessarily an accurate rendering of QCD, we will have faith only in conclusions that are robust with respect to the parameter choices.

The color, flavor, and Lorentz structure of our interaction has been taken over directly from the instanton vertex for two-flavor QCD. This interaction properly reflects the chiral symmetry of QCD: axial baryon number symmetry is broken, while chiral $SU(2) \times SU(2)$ is respected. Color is realized as a global symmetry. There are other four-fermion interactions in addition to H_I which respect the unbroken symmetries of QCD; using H_I alone is the simplest way of breaking all symmetries broken by QCD, and is therefore a good starting point.^{*)} This model of fermions interacting via a four-fermion interaction is one in the long line of such models inspired by the work of BCS as adapted to particle physics, starting with Vaks and Larkin⁷⁾ and Nambu and Jona-Lasinio⁸⁾ and studied subsequently by many others⁹⁾. There is also a tradition of modelling the low-energy dynamics of QCD, and specifically the dynamics of chiral symmetry breaking, with instanton interactions among quarks derived semi-microscopically.¹⁰⁾ This approach cannot explain the other main qualitative aspect of low-energy QCD dynamics, that is strict confinement of quarks, but it is adequate for many purposes.

§3. Chiral Symmetry Breaking and Restoration

We first consider symmetry breaking in the familiar pattern known for QCD at zero density. Working first at zero density, we choose a variational wave function of the form

$$|\psi\rangle = \prod_{\mathbf{p}, i, \alpha} \left(\cos(\theta^L(\mathbf{p})) + e^{i\xi^L(\mathbf{p})} \sin(\theta^L(\mathbf{p})) a_{L i \alpha}^\dagger(\mathbf{p}) b_{R i \alpha}^\dagger(-\mathbf{p}) \right) \left(\cos(\theta^R(\mathbf{p})) + e^{i\xi^R(\mathbf{p})} \sin(\theta^R(\mathbf{p})) a_{R i \alpha}^\dagger(\mathbf{p}) b_{L i \alpha}^\dagger(-\mathbf{p}) \right) |0\rangle, \quad (3.1)$$

with variational parameters θ and ξ depending on the modes. $a_{i\alpha}^\dagger$ and $b_{i\alpha}^\dagger$ create particles and antiparticles respectively, with flavor i and color α . This standard pairing form preserves the normalization of the wave function. The pairing occurs between particles and antiparticles with the same flavor and color but opposite helicity and opposite 3-momentum. It is in a Lorentz scalar, isospin singlet component of the chiral (2, 2) representation, *i.e.* has the σ -field quantum numbers standard in this context. Following a well-trodden path we find that the energy is minimized when

$$\tan(2\theta^L(\mathbf{p})) = \tan(2\theta^R(\mathbf{p})) = \frac{F^2(p)\Delta_\chi}{p}; \quad \xi^L(\mathbf{p}) + \xi^R(\mathbf{p}) = \pi. \quad (3.2)$$

^{*)} For example, one could add a four-fermion interaction based on one gluon exchange.⁶⁾

The full specification of ξ^R and ξ^L depends on spinor conventions. The gap parameter Δ is momentum independent and is defined by

$$\Delta_\chi \equiv 16K \int_0^\infty \frac{p^2 dp}{2\pi^2} F(p) \sin(\theta(p)) \cos(\theta(p)) . \quad (3.3)$$

(3.2) and (3.3) are consistent only if $\Delta = 0$ or if Δ satisfies the gap equation

$$1 = 8K \int_0^\infty \frac{p^2 dp}{2\pi^2} \frac{F^4(p)}{\sqrt{F^4(p)\Delta_\chi^2 + p^2}}, \quad (3.4)$$

Note that, unlike for standard pairing at a Fermi surface, this equation does not have solutions for arbitrarily weak coupling, but only for couplings above a certain threshold value. Also note that although it is common to refer to Δ_χ as the gap parameter, it is best thought of as inducing an effective quark mass, which takes the form $\Delta_\chi F^2(p)$. In the interests of simplicity of presentation, we quote all results in this paper for $\Delta_\chi = 400$ MeV; we have verified that the picture we present is qualitatively unchanged for $300 \text{ MeV} < \Delta_\chi < 500 \text{ MeV}$. Fixing Δ_χ at zero density fixes the magnitude (and sign) of the coupling K for each Λ and ν .

We now generalize this calculation to nonzero quark number density n .^{*)} It is most favorable energetically to fill the particle states up to some Fermi momentum p_F , while leaving the corresponding antiparticle states empty. That is, we replace $|0\rangle$ on the right hand side of (3.1) by $|p_F\rangle$, in which all particle states with $|\mathbf{p}| < p_F$ are occupied. The quark number density,

$$n = \frac{2}{\pi^2} p_F^3 , \quad (3.5)$$

is determined by p_F but as we shall see p_F is not equal to the chemical potential μ . The creation operators in (3.1) for modes below the Fermi surface annihilate $|p_F\rangle$, and so for these modes effectively $\theta(\mathbf{p}) = 0$. On the other hand for the unoccupied states, with $|\mathbf{p}| > p_F$, the variational scheme is unmodified. Note that the condensate does not affect n , since it pairs quarks and anti-quarks. Thus we arrive at a very simple modification of the gap equation: the lower limit of the integral in (3.4) is p_F , rather than 0. Since the interaction is ever more effectively quenched as p_F increases, the gap parameter $\Delta_\chi(p_F)$ arising as the solution of (3.4) will shrink monotonically and eventually vanish as p_F increases. Let us define n_c to be the critical density at which Δ_χ vanishes.

Having obtained a definite wave function, we can evaluate the energy density in terms of the gap parameter. Relative to the energy of the naive vacuum state $|0\rangle$, the energy density $\varepsilon(n)$ is given by

$$\frac{1}{24}\varepsilon(n) = \frac{p_F^4}{16\pi^2} + \int_{p_F}^\infty \frac{p^2 dp}{2\pi^2} \frac{p}{2} \left(1 - \frac{p}{\sqrt{\Delta_\chi^2 F^4(p) + p^2}} \right) - \frac{\Delta_\chi^2}{32K} , \quad (3.6)$$

^{*)} The reader should be warned that the next page or so is in a sense misleading; as we will see in due course the state we are about to construct is unphysical.

Fig. 1. Chiral gap (in GeV) and the pressure (in GeV^4) as a function of $p_F = (n\pi^2/2)^{1/3}$ in GeV. The pressure is positive at *very* small p_F ; it becomes negative at a p_F which is less than 0.001. At $n = n_c$, the gap vanishes and the pressure, which is still negative, has a cusp. At $n = n_0 > n_c$, the pressure crosses zero and becomes positive.

where $p_F(n)$ is to be obtained from (3.5). The chemical potential μ , the minimum energy required to add one more quark to the state, is given by $\mu = \partial\varepsilon/\partial n$ at fixed volume. We have verified that $\mu^2 = p_F^2 + \Delta_\chi^2 F^4(p_F)$. Note that $\varepsilon(0) < 0$, reflecting the fact that the physical vacuum state with its chiral condensate has a lower energy than the state $|0\rangle$. Measured relative to the physical vacuum, the energy density at nonzero n is $e(n) \equiv \varepsilon(n) - \varepsilon(0)$.

The equation for $\Delta_\chi(p_F)$ can be solved numerically, and the resulting energy evaluated. Great physical interest attaches to the pressure

$$P(n) = n \left(\frac{\partial e}{\partial n} \right) - e = n \frac{\partial}{\partial n} \left(\frac{e}{n} \right) \quad (3.7)$$

of a region with density n , where the pressure of the physical vacuum is by definition zero. For all values of the parameters that we consider reasonable, we find that after a tiny interval of very low densities at which the pressure is positive, *the pressure becomes negative, and continues to decrease until the critical density n_c* . At that point we switch over to an essentially free quark phase, in which the energy density relative to the physical vacuum is $3p_F^4/(2\pi^2) - \varepsilon(0)$, and the pressure is given by $p_F^4/(2\pi^2) + \varepsilon(0)$. At $n = n_c$, where these phases join, the pressure function is continuous, with a finite negative value, but it has a cusp. As density increases in the free-quark phase, the pressure increases monotonically, and passes through zero again at some density $n_0 > n_c$. At $n = n_0$, the energy per quark e/n is minimized and this phase is stable at zero pressure. Δ and P are shown for one set of parameters in Figure 1.

Evidently, at all but the lowest densities (which we discuss below) in the presence of a chiral condensate the negative pressure associated with increasing vacuum energy overcompensates the increasing Fermi pressure. This negative pressure signals mechanical instability of the uniform chiral symmetry broken phase. There is an attractive physical interpretation of this phenomenon. The uniform nonzero density phase will break up into stable droplets of high density $n = n_0$ in which the pressure is zero and chiral symmetry is restored, surrounded by empty space with $n = P = 0$. Although our simple calculations do not allow us to follow the evolution and eventual

stabilization of the original quark cloud, it is hard to avoid identifying the droplets of chiral symmetric phase into which it condenses with physical nucleons. Nothing within the model tells us that the stable droplets have quark number 3; nucleons are simply the only candidates in nature which can be identified with droplets within which the quark density is nonzero and the chiral condensate is zero. If correct, this identification is very reminiscent of the MIT bag philosophy, here arising in the description of a sharply defined physical phenomenon.^{*)} It seems quite different, at least superficially, from the Skyrme model, where the chiral symmetry order parameter changes in direction but not in magnitude within the nucleon.

An alternative way of reformulating the results just presented is to consider the thermodynamic potential $\Omega(\mu, \Delta_\chi)$. Values of the gap parameter Δ_χ which solve the gap equation are extrema, satisfying $\partial\Omega(\mu, \Delta_\chi)/\partial\Delta_\chi = 0$, and at these extrema $\Omega/V = -P = e - \mu n$. Using a mean field approach to evaluate Ω , the following picture emerges.²⁾ At $\mu = 0$, $\Omega(0, \Delta_\chi)$ has a minimum at $\Delta_\chi = 400$ MeV which has $P = \Omega = 0$ and $n = \partial P/\partial\mu = 0$. This is of course the vacuum solution to the gap equation. As μ is increased sufficiently, a second minimum of the potential develops at $\Delta_\chi = 0$. However, the region around the minimum describing the vacuum state remains unchanged, and this minimum continues to be the lowest possible Ω . As μ is increased further, the value of Ω at the local minimum becomes lower and lower. The lowest Ω state of the system remains unchanged (eg the system is in the vacuum state with density zero and Δ_χ unchanged) until the chemical potential is increased to $\mu_0 = p_F(n_0)$. At $\mu = \mu_0$, the local minimum of Ω at $\Delta_\chi = 0$ has $\Omega = 0$. That is, $\Omega(\mu_0, 0) = 0 = \Omega(\mu_0, 400 \text{ MeV})$. There is now a $P = \Omega = 0$ chirally symmetric phase with density n_0 . Before μ can be increased any further, the system must undergo a first order phase transition during which the density increases from zero to n_0 . At all intermediate densities, the system is in a mixed phase in which there are regions with density n_0 and regions with density zero. Once the transition is completed, μ can rise further, and the lowest Ω configuration becomes one with $\Omega < 0$, that is with positive pressure, in which $n > n_0$.

What, then, of the negative pressure phase constructed previously? This solution to the gap equation is a local *maximum* of Ω , with $\Omega > 0$ and $P < 0$. Were one to somehow construct it, it would immediately fall apart into a mixture of the two stable phases. The description of the preceding paragraph allows one to arrive at the correct description of the system (density zero, or density n_0 , or mixture of the two) without ever constructing an unphysical uniform state with n and Δ_χ nonzero.

Finally, what of the positive pressure phase at very low density? This dilute gas of quarks with mass $\Delta(0)$ has $\mu > \Delta(0) > \mu_0$. At this large value of μ , Ω has two nondegenerate minima. The low density gas of constituent quarks is one; the other is a phase with $n > n_0$, and it is this dense phase which has the lower Ω . The low density gas of constituent quarks could only be reached if, as μ is increased above μ_0 , the phase transition to the favored high density chirally symmetric phase does

^{*)} Considerations similar to those we describe also lead Buballa¹¹⁾ to conclude that in a Nambu Jona-Lasinio model with an interaction which differs from the one we use, matter with broken chiral symmetry is unstable and nucleons can therefore only be viewed as bags within which chiral symmetry is restored.

not occur until μ is increased so high as to be above $\Delta_\chi(0)$.

The picture we find is satisfying since the model finds a way to avoid having a phase with unconfined constituent quarks even though we have not included confinement in any explicit sense. This nice result is not obtained for all parameter values, however. For example, for $\nu = 1$ and $\Lambda > 2.2$ GeV, we find that $\mu_0 > \Delta_\chi$. That is, the vacuum phase becomes a gas of constituent quarks at a lower μ than that at which the chirally symmetric high density phase takes over. One has a mixed phase of droplets within which chiral symmetry is restored surrounded by regions not of vacuum but of regions with a nonzero density of constituent quarks. It is fortunate that these parameter ranges seem unreasonable.

At a quantitative level, a naive implementation of our proposed identification of droplets of $n = n_0$ matter with nucleons works surprisingly well. One might want to identify n_0 with the quark density at the center of baryons. Taking this to be two(three) times nuclear matter density yields $p_F(n_0) \sim 0.34(0.39)$ GeV. On the other hand, requiring $e(n_0)/n_0$ to be one third the nucleon mass yields $p_F(n_0) \sim 0.31$ GeV. Our toy model treatment cannot meet both criteria simultaneously, which is not surprising, but the magnitude of $p_F(n_0)$ is very reasonable, ranging from 0.27 to 0.36 for the parameters we have considered. The vacuum energy, which becomes the bag constant, is also reasonable in magnitude. Adding further interactions to H_I would obviously make a quantitative difference but the qualitative picture will not change, at least as long as the instanton interaction is the dominant one.

In any case, the physical picture suggested here has significant implications for the phase transition, as a function of density, to restored chiral symmetry. Since the nucleons are regions where the symmetry is already restored, the transition should occur by a mechanism analogous to percolation as nucleons merge.¹²⁾ In other words, nuclear matter is midway through the first order phase transition described above, and chiral symmetry restoration is nothing more than completing this transition. This transition should be complete once a density characteristic of the center of nucleons is achieved. As n increases, the fraction of the volume of space occupied by the $n = n_0$ phase increases. In our toy model, the chemical potential and the pressure remain constant as n is increased from that of nuclear matter, which is in the mixed phase, to n_0 . This reflects the fact that we have neglected interactions between droplets. In nature, once these are included, some external pressure must be imposed in order to induce the nucleons to merge.*)

*) There is a related reason that interactions between droplets are needed. Although it is very nice to see the model favoring quarks “confined” into droplets within which they have zero mass rather than free as constituent quarks, it is asking too much of this toy model to expect it to correctly predict that nature favors droplets containing three quarks. However, augmenting the model to include a short range repulsion between droplets would make it unfavorable for small droplets to merge into bigger ones, and would mean that in the mixed phase the favored droplets are the smallest possible droplets. A model with color introduced only as a global symmetry cannot select 3-quark-droplets, but it would nevertheless be interesting to see it favoring small droplets over large ones. One way of introducing such an effect would be to introduce a negative surface tension for the interface between the $n = n_0$ phase and the vacuum. With a negative surface tension, in the mixed phase the system will maximize the ratio of droplet surface to droplet volume, and will therefore consist of the smallest possible droplets of the $n = n_0$ phase surrounded by vacuum. A

The mechanism of chiral symmetry restoration at finite density but zero temperature is quite different from the one we expect at finite temperature and zero density: it occurs by percolation among pre-formed bags of symmetric phase. In the toy model we have described, this transition seems perfectly smooth. As the density increases, one phase steadily wins over the other. In the chiral limit, however, this cannot be the whole story. At zero density, chiral symmetry is broken. At $n = n_0$ when the dense phase has taken over completely, chiral symmetry is restored. At what density (that is at what volume ratio of the two phases in the mixed phase regime) is chiral symmetry restored? This question cannot be answered precisely using the methods we have developed to this point. It is plausible, however, that as soon as the density is high enough that there are no longer vacuum regions of infinite spatial extent, chiral symmetry is restored. Once one has only isolated vacuum regions, each of these isolated regions can have the chiral order parameter pointing in different directions in isospin space. Each isolated region will pick a different σ direction. This means that in the system as a whole, chiral symmetry will be restored. In this sense, what matters is the “unpercolation” of the vacuum rather than the percolation of the droplets. Regardless of the precise criterion, the density n_χ at which chiral symmetry restoration occurs must be somewhat less than n_0 . At densities less than n_χ , one has massless pions — oscillations of the orientation of the condensate present in the vacuum regions of infinite spatial extent associated with spontaneous chiral symmetry breaking. At higher densities $n > n_\chi$, the pions need no longer be massless. It is a logical possibility that the restoration of chiral symmetry at $n = n_\chi$ is a second order transition, occurring within the “larger” first order transition. It is also a logical possibility that the chiral symmetry restoration transition is first order, between two phases with density n_χ^- and n_χ^+ , again within the larger first order transition between $n = 0$ and $n = n_0$. Of course, away from the chiral limit, with a nonzero current quark mass and a nonzero pion mass, the transition can be completely smooth.

§4. Color Superconductivity

At high density, pairing of particles near the Fermi surface as in the original BCS scheme becomes more favorable. Our Hamiltonian supports condensation in quark-quark channels. The condensation is now between fermions with the same helicity, and the Hamiltonian selects chiral isosinglets — that is, antisymmetry in flavor. One can therefore have spin 0 — antisymmetric in spin and therefore in color, forming a $\bar{\mathbf{3}}$, or spin 1 — symmetric in spin and therefore in color, forming a $\mathbf{6}$.

We first consider the former. A suitable trial wave function is^{*)}

$$|\psi\rangle = G_L^\dagger G_R^\dagger |p_F\rangle \quad (4.1)$$

negative surface tension (or short range droplet-droplet repulsion introduced in some other way) will not upset the stability of either the vacuum or of the uniform phase with density $n = n_0$; it simply upsets the stability of a mixed phase with one large droplet relative to one with many smaller ones.

^{*)} Nothing misleading here; there will be no negative pressure and no droplet formation here; the state we are about to construct is stable.

where

$$\begin{aligned}
G_L^\dagger &= \prod_{\alpha,\beta,\mathbf{p}} \left(\cos(\theta_A^L(\mathbf{p})) + \varepsilon^{\alpha\beta 3} e^{i\xi_A^L(\mathbf{p})} \sin(\theta_A^L(\mathbf{p})) a_{L1\alpha}^\dagger(\mathbf{p}) a_{L2\beta}^\dagger(-\mathbf{p}) \right) \\
&\quad \left(\cos(\theta_B^R(\mathbf{p})) + \varepsilon^{\alpha\beta 3} e^{i\xi_B^R(\mathbf{p})} \sin(\theta_B^R(\mathbf{p})) b_{R1\alpha}^\dagger(\mathbf{p}) b_{R2\beta}^\dagger(-\mathbf{p}) \right) \\
&\quad \left(\cos(\theta_C^R(\mathbf{p})) + \varepsilon^{\alpha\beta 3} e^{i\xi_C^R(\mathbf{p})} \sin(\theta_C^R(\mathbf{p})) a_{R1\alpha}^\dagger(\mathbf{p}) a_{R2\beta}^\dagger(-\mathbf{p}) \right) \quad (4.2) \\
G_R^\dagger &= \text{same, with } R \leftrightarrow L.
\end{aligned}$$

Here, α and β are color indices, and we have chosen to pair quarks of the first two colors. 1 and 2 are flavor indices. The first term in (4.2) creates particles above the Fermi surface; the second creates antiparticles; the third creates holes below the Fermi surface. In this state, the Lorentz scalar $\langle q^{i\alpha} C \gamma^5 q^{j\beta} \varepsilon_{ij} \varepsilon_{\alpha\beta 3} \rangle$ is nonzero. This singles out a preferred direction in color space and breaks color $SU(3) \rightarrow SU(2)$. The $U(1)$ of electromagnetism is spontaneously broken but there is a linear combination of electric charge and color hypercharge under which the condensate is neutral, and which therefore generates an unbroken $U(1)$ gauge symmetry. No flavor symmetries, not even the chiral ones, are broken.

Note that n is now not given by (3.5) because the operators in (4.2) can change particle number. Varying the expectation value of $H - \mu N$ in this state with respect to p_F yields $p_F = \mu$, unlike in the case of the chiral condensate. This difference reflects the fact that a gap in a $\langle qq \rangle$ channel does not act as an effective mass term in the way that a chiral gap does. Upon adding a quark, the condensate can adjust in such a way that the energy cost is only p_F . There is, however, a true gap in the sense of condensed matter physics: the energy cost of making a particle-hole excitation is $2\Delta F^2(\mu)$ at minimum. Varying with respect to all the other variational parameters yields $\xi_{A,B,C}^R + \xi_{A,B,C}^L = \pi$, $\theta_{A,B,C}^R = \theta_{A,B,C}^L$, and

$$\tan(2\theta_A^L(\mathbf{p})) = \frac{F^2(p)\Delta}{p - \mu}, \quad \tan(2\theta_B^L(\mathbf{p})) = \frac{F^2(p)\Delta}{p + \mu}, \quad \tan(2\theta_C^L(\mathbf{p})) = \frac{F^2(p)\Delta}{\mu - p}. \quad (4.3)$$

Here, the gap Δ satisfies a self-consistency equation of the form

$$\begin{aligned}
1 = \frac{K}{\pi^2} \left\{ \int_\mu^\infty \frac{F^4(p)p^2 dp}{\sqrt{F^4(p)\Delta^2 + (p - \mu)^2}} + \int_0^\infty \frac{F^4(p)p^2 dp}{\sqrt{F^4(p)\Delta^2 + (p + \mu)^2}} \right. \\
\left. + \int_0^\mu \frac{F^4(p)p^2 dp}{\sqrt{F^4(p)\Delta^2 + (\mu - p)^2}} \right\}. \quad (4.4)
\end{aligned}$$

The three terms in this equation arise respectively from particles above the Fermi surface, antiparticles, and particles below the Fermi surface. For $\mu > 0$ the particle and hole integrals diverge logarithmically at the Fermi surface as $\Delta \rightarrow 0$, which signals the possibility of condensation for arbitrarily weak attraction.

Because the numerical coefficient in the gap equation is smaller than the threshold value at which one would have a nonzero Δ_χ at $\mu = 0$, Δ would be zero were it not for the logarithmically divergent contribution to the integral from the

Fig. 2. Gap created by the Lorentz scalar color superconductor condensate, as a function of $\mu = p_F$ for $\nu = 1$ and (from left to right) $\Lambda = 0.4, 0.8$ GeV. Each curve begins where n is given by the appropriate n_0 .

region near μ . This means that at small μ , the gap must be small because the density of states at the Fermi surface is small. This has only formal significance, because the only densities of physical relevance are $n = 0$ and $n \geq n_0$. At intermediate densities, matter is in an inhomogeneous mixture of the $n = 0$ and $n = n_0$ phases. As μ increases, the density of states at the Fermi surface increases and the gap parameter grows. Finally, at large μ the effect of the form factor F is felt, the effective coupling decreases, and the gap parameter goes back down. For the parameter ranges we have examined the gap parameter is quite substantial: $\sim 50 - 150$ MeV at n_0 , and peaking at $100 - 200$ MeV at a density somewhat higher. We plot Δ for two sets of parameters in Figure 2. The density at which the gap peaks depends on Λ ; the shape of the curve depends on ν ; the height of the curve is almost independent of both.

As in the previous section, one can obtain expressions for the energy and the density, and thus derive the equation of state. We find that the equation of state is hardly modified from the free-quark values — the presence of the condensate typically lowers the energy density by several tens of MeV per fm^3 and the pressures, at equal baryon density, are equal to within a few per cent. This makes it very plausible that the color condensation makes only a small change in the density n_0 at which a stable phase exists at zero pressure. We have made this argument more rigorous by doing a calculation in which we consider chiral and color condensation simultaneously.²⁾

The third color has so far been left out in the cold, but we can gain energy by allowing it too to condense. The available channel is the color **6**. There is attraction in this channel,¹⁾ for a pairing that is a spatial axial vector. The resulting condensate spontaneously breaks both color and rotational symmetry. Without modification, our model suggests that this axial vector gap is of order a few keV at most,¹⁾ orders of magnitude smaller than the scalar color breaking condensate. This is not a robust result, and it is worth exploring whether plausible interactions can be added to H_I which strengthen the axial vector condensate.

In looking for signatures of color superconductivity in heavy ion physics and in neutron stars, it is unfortunate that the equation of state is almost equal to that for a deconfined phase with no diquark condensate. Superconducting condensates do modify the gauge interactions and this may have implications in heavy ion collisions. In our model as it stands, color is realized as a global symmetry. Breaking of this

symmetry generates Nambu-Goldstone bosons, formally. However, in reality color is of course a gauge symmetry, and the true spectrum does not contain massless scalars, but rather massive vectors. There is a residual $SU(2)$ gauge symmetry, presumably deconfined, and there are five gluons whose mass is set by the scalar condensate. The scalar condensate carries electric as well as color charge. It is neutral under a certain combination of electrodynamic and color hypercharge. If densities above n_0 are achieved at low enough temperatures that the scalar condensate forms, there will be a mixture of the ordinary photon and the color hypercharge gauge boson which is massless. Either the modification of the photon or the loss of massless gluons could have consequences, but dramatic effects do not yet seem apparent. Recently, we have described another possible signature.¹³⁾ The formation of a color superconducting state lowers the energy most if the matter is up-down symmetric. In a heavy ion collision, in which down quarks initially exceed up quarks, as a color superconductor condensate forms in the densest region near the center of the collision it may therefore expel a few down quarks and up anti-quarks into the surrounding less dense regions. These will eventually become negative pions. When the condensate breaks up late in the collision, it likely yields equal numbers of protons and neutrons. The total number of protons in the final state will then be more than twice 79. Experimentalists should therefore look for event-by-event correlation between observables which suggest high density and low temperature on the one hand, and either an increase in the number of protons per event or an increase in the π^-/π^+ ratio on the other.

Turning to neutron star phenomenology, the slowness of observed neutron star cooling rates may indicate that a gap in the excitation spectrum for quark matter might be welcome,¹⁴⁾ as this suppresses neutrino emission via weak interaction processes involving single thermally excited u and d quarks by $\exp(-\Delta/T)$.

§5. Discussion

Many things were ignored in this analysis. Most important, perhaps, is the strange quark. Whatever the interaction(s), color superconductivity in a three flavor theory necessarily introduces the new feature of flavor symmetry breaking. The condensates considered in our two-flavor model are flavor singlets; this is impossible for a $\langle qq \rangle$ condensate in a three flavor theory. One particularly attractive possibility is condensation in the $\langle q_i^\alpha C \gamma^5 q_j^\beta \varepsilon^{ijA} \varepsilon_{\alpha\beta A} \rangle$ channel, with summation over A . This breaks flavor and color in a coordinated fashion, leaving unbroken the diagonal subgroup of $SU(3)_{\text{color}} \times SU(3)_{\text{flavor}}$.

Another question concerns the postulated Hamiltonian. While there are good reasons to take an effective interaction of the instanton type as a starting point, there could well be significant corrections affecting the more delicate consequences such as axial vector **6** condensation. A specific, important example is to compare the effective interaction derived from one-gluon exchange. It turns out that this interaction has a similar pattern, for our purposes, to the instanton: it is very attractive in the σ channel, attractive in the color antitriplet scalar, and neither

attractive nor repulsive in the color sextet axial vector. More generally, it would be desirable to use a renormalization group treatment to find the interactions which are most relevant near the Fermi surface.

The qualitative model we have treated suggests a compelling picture both for the chiral restoration transition and for the color superconductivity which sets in at densities just beyond. It points toward future work in many directions: chiral symmetry restoration via the percolation (of baryons) or unpercolation (of the vacuum) must be further characterized; consequences in neutron star and heavy ion physics remain to be elucidated; the superconducting ordering patterns may hold further surprises, particularly as flavor becomes important.

Acknowledgements

I would like to thank Tsuneo Suzuki and the other organizers of YKIS 97, first for arranging such a stimulating workshop, and second for giving me the opportunity to visit Japan for the first time, which I very much enjoyed. I am very grateful to my collaborators M. Alford, F. Wilczek and J. Berges. Exploring this terrain with them has been great fun. I also wish to acknowledge helpful conversations with S. Pratt, who suggested the possibility of negative surface tension, and with M. Gyulassy, R. L. Jaffe, M. Prakash, R. Rapp, H. Satz, T. Schäfer, R. Seto, E. Shuryak, D. T. Son, M. Stephanov, M. Velkovsky and I. Zahed. This research is supported in part by DOE cooperative research agreement DE-FC02-94ER40818.
